Abstract

Hydraulic engineering infrastructures are usually of concern to many people and are likely to interfere with the environment. Moreover, they are supposed to keep on functioning for many years. In times of rapid societal and environmental change this implies that sustainability and adaptability are important attributes. These are central to Building with Nature (BwN), an innovative approach to hydraulic engineering infrastructure development and operation. Starting from the natural system and making use of nature's ecosystem services, BwN attempts to meet society's needs for infrastructural functionality, and to create room for nature development at the same time. By including natural components in infrastructure designs, flexibility, adaptability to changing environmental conditions and extra functionalities and ecosystem services can be achieved, often at lower costs on a life-cycle basis than 'traditional' engineering solutions. The paper shows by a number of examples that this requires a different way of thinking, acting and interacting.

Keywords: sustainability, infrastructure, hydraulic engineering, ecosystem services, design

1. Introduction

Present-day trends in society (urbanization of delta areas, growing global trade and energy demand, stakeholder-emancipation, etc.) and in the environment (reducing biodiversity, climate change, accelerated relative sea level rise, etc.) put ever higher demands on engineering infrastructures. Mono-functional solutions designed without due consideration of the surrounding system are no longer accepted. Sustainability, multi-functionality and stakeholder involvement are required instead. This trend equally applies to hydraulic engineering works and the associated water system management.

The design of hydraulic engineering projects is no longer the exclusive domain of hydraulic engineers. Collaboration with other disciplines, such as ecology, economy, social sciences and administrative sciences is crucial to come to acceptable solutions. The specialists involved in such design projects must learn how to put forward their expertise in much more complex decision making processes than before: being right according to the laws of physics no longer

guarantees being heard in such processes. If this reality is ignored, it may lead to long and costly delays of projects, as stakeholders and other interested parties are becoming ever more proficient in using the legal opportunities to oppose developments and have decisions postponed. In the Netherlands the court-cases that delayed the realisation of the extension of the Rotterdam harbour taught an expensive lesson, keeping the investments in the initiation, planning and design phases of the project without any return for a long time.

This and other experiences triggered the awareness that projects should be developed differently, with nature and stakeholder interests incorporated right from the start. In other words: from a reactive approach, minimizing and mitigating the impacts of a set design, to a pro-active one, optimizing on all functions and ecosystem services. Although in principle the concept of Building with Nature (BwN) is broader than hydraulic engineering, we will focus here on water-related projects. This paper, which is an extension of De Vriend (2013), discusses the design steps as they have been suggested by the BwN innovation programme and illustrates their use by describing a number of hydraulic engineering projects in which the concept has been tested and some other examples where successful application is to be expected.

46 2. The Building with Nature (BwN) concept

47 2.1. General principles

48 Building with Nature (BwN) is about meeting society’s in-
49 frastructural demands by starting from the functioning of
50 the natural and societal systems in which this infrastruc-
51 ture is to be realized. The aim is not only to comply with
52 these systems, but also to make optimum use of them and
53 at the same time create new opportunities for them. This
54 approach is in line with the need to find different ways
55 of operation and it requires a different way of thinking,
56 acting and interacting (De Vriend and Van Koningsveld,
57 2012; De Vriend et al., 2014).

58 *Thinking* Thinking does not start from a certain design
59 concept focusing on the primary function, but rather from
60 the natural system, its dynamics, functions and services,
61 and from the vested interests of stakeholders. Within this
62 context, one seeks optimal solutions for the desired infra-
63 structural functionality.

64 *Acting* The project development process requires different
65 acting, because it is more collaborative and extends bey-
66 ond the delivery of the engineering object. The natural
67 components embedded in the project will take time to de-
68 velop afterwards, and one has to make sure they function
69 as expected. Post-delivery monitoring and projections into
70 the future are an integral part of the project. This also cre-
71 ates opportunities to learn a lot more from these projects
72 than from traditional ones.

73 *Interacting* BwN project development is a matter of co-
74 creation between experts from different disciplines, prob-
75 lem owners and stakeholders (e.g., Temmerman et al.,
76 2013). This requires a different attitude of all parties in-
77 volved and different ways of interaction, in interdisciplin-
78 ary collaborative settings rather than each actor taking
79 away his task and executing it in relative isolation.

80 2.2. Design steps

81 Project development, albeit iteratively, generally goes
82 through a number of consecutive phases. The BwN innov-
83 ation programme distinguished ‘initiation’, ‘planning and
84 design’, ‘construction’ and ‘operation and maintenance’,
85 but other distinctions are equally suitable. BwN solutions
86 may be introduced in each project phase in the form of
87 ecologically preferable and more sustainable approaches.
88 Although there is room for improvement in any phase, the
89 earlier the approach is embraced in the project develop-
90 ment process, the greater its potential impact.

91 An important starting point for any development should
92 be the environment at hand. A key characteristic that dis-
93 tinguishes a BwN design from other integrated approaches

94 is the proactive utilization and/or provision of ecosys-
95 tem services as part of the engineering solution. The fol-
96 lowing design steps were developed, tested and suppor-
97 ted by scientific knowledge in the BwN innovation pro-
98 gramme (De Vriend and Van Koningsveld, 2012; Eco-
99 Shape, 2012):

- Step 1: Understand the system (including ecosystem 100
services, values and interests). 101
 - The system to be considered depends on the pro- 102
ject objectives 103
 - Information about the system at hand can- 104
/should be derived from various sources (his- 105
toric, academic, local etc.) 106
 - Look for user functions and eco-system services 107
beyond those relevant for the primary objective 108
- Step 2: Identify realistic alternatives that use and/or 109
provide ecosystem services. 110
 - Take an inverted perspective and turn tradi- 111
tional reactive perspectives into proactive ones 112
utilizing and/or providing ecosystem services 113
 - Involve academic experts, field practitioners, 114
community members, business owners, decision 115
makers and other stakeholders in the formulation 116
of alternatives 117
- Step 3: Evaluate the qualities of each alternative and 118
preselect an integral solution. 119
 - More value does not necessarily imply higher 120
construction cost 121
 - Dare to embrace innovative ideas, test them and 122
show how they work out in practical examples 123
 - Perform a cost-benefit analysis including valu- 124
ation of natural benefits 125
 - Involve stakeholders in the valuation and selec- 126
tion process 127
- Step 4: Fine-tune the selected solution (practical re- 128
strictions and the governance context). 129
 - Consider the conditions/restrictions provided by 130
the project (negotiable/non-negotiable) 131
 - Implementation of solutions requires involve- 132
ment of a network of actors and stakeholders 133
- Step 5: Prepare the solution for implementation in 134
the next project phase. 135
 - Translate solution to a technical design 136
 - Prepare an appropriate request for proposals, 137
terms of reference or contract (permitting) 138
 - Organise required funding (multi-source) 139
 - Prepare risk analysis and contingency plans 140

Figure 1: Range of potential BwN applications along the main axes of given bed slope and hydrodynamic energy. Of course factors like salinity and geo-climatic region also determine potential solutions.

141 Fundamental to the above design steps is a thorough knowl- 170
 142 edge of how the natural system functions and a correct 171
 143 interpretation of the signals to be read from its behaviour. 172
 144 The latter may indicate in what direction the system is 173
 145 evolving, how best to integrate the desired infrastructure 174
 146 into it and how to make use of the ecosystem services avail- 175
 147 able. They may also provide an early warning of adverse 176
 148 developments, however, or indicate an increased sensitivity 177
 149 to natural hazards. Investing in increased understanding 178
 150 of the natural system and its inherent variability does not 179
 151 only pay off to the realisation of the project at hand, but 180
 152 also to the system's overall management. 181

153 *2.3. Spectrum of applicability*

154 What kind of BwN solution may be applied in a given situ- 182
 155 ation, be it coastal or riverine, sandy or muddy or domi- 183
 156 nated by living components, is governed by the surround- 184
 157 ing physical environment. Practical experience has shown 185
 158 that four parameters, being: bed slope, hydrodynamic en- 186
 159 ergy, salinity and geo-climatic region (e.g., temperate or 187
 160 tropical), span up a range of potential applications (see 188
 161 Figure 1). 189

162 *Flat slopes* In low slope environments generic BwN solu- 193
 163 tions can be completely sediment based. This is true for 194
 164 both saline and fresh water systems. Differentiating is pos- 195
 165 sible according to energy levels. High energy tidal envi- 196
 166 ronments favour designs that are wide and of high sediment 197
 167 volume (kilometres scale) in order to produce equilibrium 198
 168 shorelines and slopes, and enough bulk volume to with- 199
 169 stand extreme conditions (for example parts of the Dutch

coastline with beaches and dunes, sand engine). Where 170
 these high energy exposed systems are typically low in 171
 biomass, the low energy sheltered environments, saline or 172
 fresh, allow soft solutions with high biomass, lower width 173
 (hundreds of meters) and with tendencies to accrete cohes- 174
 ive sediment. This often results in a mix of sand and mud, 175
 stabilized by (root systems of) vegetation cover. 176

Moderate slopes If the bed slope increases, maximum 177
 width for the soft foreshore in the wave impact zone is 178
 reduced. To maintain safety against flooding, for exam- 179
 ple, hybrid solutions are required, such as a 'stable 180
 sediment foreshore with hard dike' combination. Wave 181
 reduction on the foreshore enables dikes to be lower and 182
 softer (e.g., grass-clay cover) than traditional engineering 183
 designs. The foreshores in these solutions can typically 184
 be stabilized through vegetation and/or reef-structures 185
 (e.g., a 'sediment nourishment-wave-reducing floodplain 186
 forest-dike' combination in fresh water, or a sediment 187
 nourishment-stabilizing and wave reducing oyster reef- 188
 mangrove-saltmarsh-dike systems in saline water). The 189
 selection of the living components of the application is ob- 190
 viously dependent on the geo-climatic system relevant for 191
 the case. 192

Steep slopes If the bed slope increases further, hard solu- 193
 tions could eventually prevail as most suitable solution. It 194
 is possible, however, to introduce ecological enhancements 195
 on hard solutions, in order to increase habitat diversity, 196
 biodiversity or productivity of the structures. This could 197
 result in interesting combinations of safety, economic and 198
 natural win-win solutions. 199

200 The following sections describe examples for a number of
 201 distinct environments. We will indicate what role Design
 202 Step 1, reading (or not reading) the natural system, has
 203 played. For each environment a distinct example is de-
 204 scribed, followed by a brief analysis of the potential for
 205 more general application.

206 3. BwN in riverine environments

207 3.1. Example: Room for the River

208 Floodplains of lowland rivers are very attractive areas for
 209 development. This explains why in the past centuries,
 210 man has encroached on these rivers and deprived them
 211 from large parts of their floodplains (Figure 2). As a
 212 consequence of the reduced storage capacity, flood waves
 213 in these rivers become higher and proceed faster (Fig-
 214 ure 3, showing the same floodwave in the Upper Rhine
 215 with an old and a recent river geometry), thus increasing
 216 the hydrodynamic load on the flood defences and reducing
 217 the lead time for precautionary measures such as evacu-
 218 ation.

Figure 2: Urban encroachment on the Rhine branches near the city of Arnhem, NL, between 1830 and 2000 (from: Silva et al. (2001)).

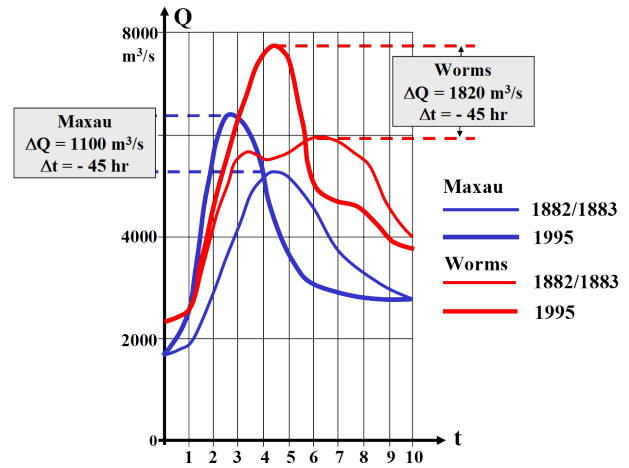

Figure 3: Computed flood wave in the Upper Rhine, Germany, with the river geometry of 1882/1883 and 1995 respectively (adapted from ICHR (1993))

219 The traditional response to these trends is to raise and
 220 strengthen the embankments. This is basically a reactive
 221 approach, as it does not remove the cause of the problem,
 222 viz. the lack of storage capacity.

223 In recent years, governments and managers of various
 224 rivers around the world have recognized this and have
 225 started proactive floodplain restoration projects, some-
 226 times primarily driven by the need for flood alleviation,
 227 in other cases by the wish to restore nature or both (for
 228 instance, see Room for the River (2012) for the Dutch
 229 Rhine branches, or Mississippi (2013), or Schneider (2007)
 230 for the Danube).

231 In case of the Rhine and Meuse rivers in the Netherlands,
 232 extensive schemes have been developed to reconnect re-
 233 moved floodplain area to the river, thus restoring storage
 234 capacity. Part of the returned floodplain area was made
 235 available to nature development, provided that this did
 236 not unacceptably reduce the river's flood conveyance ca-
 237 pacity.

238 Clearly, the signals of nature (like in Figure 3) have been
 239 read and understood in this case. It is also an example
 240 of thinking, acting and interacting differently. Thinking
 241 differently, because this goes against the traditional reac-
 242 tive approach (acting after a problem has become mani-
 243 fest). Acting differently, because different measures are
 244 taken, such as floodplain lowering, side channel digging
 245 and dike displacement. And interacting differently, be-
 246 cause other parties (e.g. Non Governmental Organisa-
 247 tions (NGOs), terrain managers, recreation organisations,
 248 inhabitants) are actively involved in decision making on
 249 these projects.

250 3.2. More general applicability

251 Flood alleviation and nature restoration are not the only
 252 river issues. Dam building, excessive water offtake, sand
 253 mining and normalisation are activities that profoundly
 254 influence river behaviour, thus evoking a variety of problems.
 255 Immediate effects concern the flow regime and the
 256 sediment transport capacity, but in the longer run the
 257 large-scale morphology is affected. Especially changes of
 258 the longitudinal slope can have severe consequences. The
 259 river may incise, which leads to erosion and groundwater
 260 level drawdown, e.g. downstream of dams. In other cases,
 261 the river bed builds up far above the surrounding area,
 262 leading to an increased flood risk, as has become manifest
 263 during the 2010 Indus flood (Figure 4).

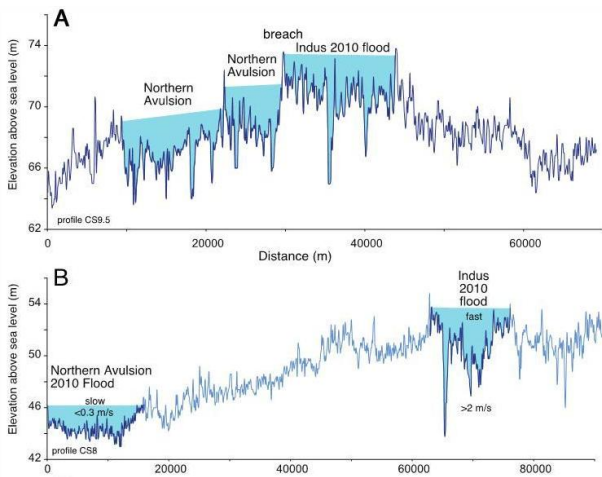

Figure 4: Landscape profiles across the Indus, Pakistan, and the avulsions during the 2010 flood (from: Syvitski and Brakenridge (2013)).

264 Also, the cross-sectional area and the flood conveyance capacity
 265 can be severely reduced, which further enhances the
 266 flood risk. An example of the latter is the Lower Yellow
 267 River near Huayankou, China (Figure 5), where a peak dis-

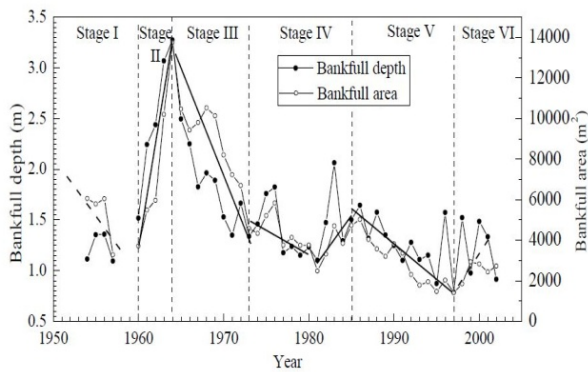

Figure 5: Time-evolution of depth and cross-sectional area of the Lower Yellow River at Huayankou Station, China; the stages refer to different regimes of dam operation (from: Ma et al. (2012))

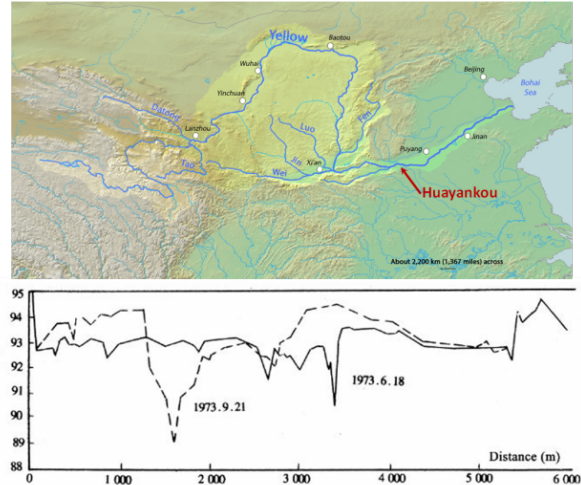

Figure 6: Cross-section of the Lower Yellow River at Huayankou, China, before and after the 1973 flood (from: IRTCES (2005))

268 charge of $7.860 \text{ m}^3/\text{s}$ in 1996 gave about the same peak water
 269 level as a peak discharge of $22.300 \text{ m}^3/\text{s}$ in 1958.

270 In order to deal with these problems, the river has to
 271 be read in terms of flow discharge, sediment transport
 272 and (large-scale) morphological behaviour. Water man-
 273 agement has to be attended with corresponding sedi-
 274 ment management in order to avoid problems as described
 275 above. Being part and parcel of the river bed, the flood-
 276 plains also need to be managed carefully, as they will play
 277 an important role in storing and conveying flood waters,
 278 whereas in the meantime they may support a valuable eco-
 279 system and/or important economic activities such as agri-
 280 culture.

281 The managers of the Yellow River have understood this,
 282 in that they noted that heavily sediment-laden floods tend

Figure 7: Man-made flood generation in the Yellow River at Xiaolangdi, China. The highly sediment-laden flow scours the river channel over a long distance downstream

283 to scour the river bed (Figure 6). After the construction of
284 the Xiaolangdi Dam, they flush the river from time to time
285 by creating so-called man-made floods. Through joint op-
286 eration of three consecutive reservoirs, they create a flood
287 wave and at the same time release large amounts of sedi-
288 ment from the reservoirs (Figure 7). The resulting highly
289 concentrated flow, scours the river bed over a large dis-
290 tance, thus restoring the river’s conveyance capacity for
291 natural floods.

292 4. BwN in sandy shore environments

293 4.1. Example: The Delfland Sand Engine

294 Since the 1990’s, the Holland coast, an exposed sandy dune
295 coast bordering the North Sea, is maintained by nourish-
296 ing it with sand taken from offshore. In principle, this
297 is a nature-friendly and sustainable way of coastal main-
298 tenance, even in times of sea level rise. Yet, present-day
299 practice is reactive: whenever the coastline threatens to
300 withdraw behind a given reference line, a relatively small
301 amount of sand (up to a few million m^3) is placed on the
302 beach or the upper shoreface. A typical return period of
303 these nourishments is some five years. This practice has
304 a few disadvantages. Every nourishment buries part of
305 the marine ecosystem, the recovery of which takes several
306 years. As a consequence, five-yearly nourishments tend to
307 bring the ecosystem into a more or less permanent state of
308 disturbance (Baptist et al., 2008). Moreover, nourishing
309 only the upper part of the shoreface tends to lead to over-
310 steepening of the coastal profile, hence to more offshore-
311 directed sediment transport and, in the long run, the nec-
312 essity to nourish ever more frequently. Or, otherwise,
313 this over-steepening leads to an increased susceptibility to
314 coastal erosion when the nourishments stop (Stive et al.,
315 1991).

316 In 2011, the Province of Zuid-Holland and Rijkswaterstaat
317 started an experiment to find out whether nourishing a
318 large amount at once is a better solution. Between Febru-
319 ary and July 2011, 21.5 million m^3 of sand was deposited
320 on the shoreface in front of the Delfland coast, between
321 The Hague and Rotterdam (Figure 8). The idea of this
322 mega-nourishment is that in the coming decades the sand
323 will be distributed by waves, currents and wind decades
324 over this 18 km long coastal reach, thus feeding the lower
325 shoreface, as well as the subaqueous and subaerial beach
326 and the dune area. Once the nourishment has been placed,
327 the ecosystem is expected to suffer less than in the case
328 of repeated small nourishments. The experiment should
329 provide an answer to the question to what extent the dis-
330 advantage of the earlier investment (the costs of the nour-
331 ishment) will be outweighed by additional benefits, such as
332 less harm done to or even new opportunities for the ecosys-
333 tem, recreational opportunities (for instance, the Sand En-
334 gine has soon become a favourite site for kite surfers, which

Figure 8: Upper panel: The Delfland Sand Engine shortly after placement (July 2011). Lower panel: The Sand Engine has evolved into an almost symmetrical salient (October 2013). (Source: <https://beeldbank.rws.nl>, Rijkswaterstaat / Joop van Houdt)

brings profit to the local economy), a wider dune area (i.e. also a larger freshwater reserve) and a better adaptation of the coastal defence system to sea level rise.

A recent morphological survey showed that in the two years since construction about 2 million m^3 of sand (i.e. some 10% of the total volume) have moved, of which 0.6 million have stayed on the Sand Engine, 0.9 million in its immediate vicinity and 0.5 million have been transported outside the survey area, i.e. to the dune area or to deeper water, which agrees well with earlier model predictions (e.g. Stive et al. (2013a,b)). As coastline processes tend to slow down as they approach the equilibrium state (in this case a straight coastline), these results suggests that a lifetime estimate of 20 years is probably conservative.

Ecologically speaking, the Sand Engine exhibits interesting developments (Linnartz, 2013), e.g. juvenile dune formation and establishment of pilot vegetation, including rare species. It also turns out to be a favourite resting area for birds and sea mammals, and the lagoon is full of juvenile fish. Whether the Sand Engine approach is economically attractive remains to be seen. First calculations (Stive, 2013, private communication) suggest that,

358 even if only the costs of sand reaching the shore are consid- 382
 359 ered, the economy of scale and the presence of heavy 383
 360 equipment in the vicinity (building Maasvlakte II, a sea- 384
 361 ward extension of Rotterdam harbour) outweigh the effect 385
 362 of discounting the early investment. 386

363 *4.2. More general applicability*

364 The concept and the way of thinking underlying the Sand 390
 365 Engine are generic for eroding sandy coasts, but its design 391
 366 cannot simply be copied to other locations. The design 392
 367 should rather comply with the local situation and the local 393
 368 dynamics. Moreover, not only sea level rise may be the 394
 369 cause of coastal erosion, but also a lack of sediment sup- 395
 370 ply, e.g. due to damming or sand mining in rivers feeding 396
 371 the coast, or interruption of the longshore drift by engi- 397
 372 neering structures), or removal of stabilizing vegetation 398
 373 (mangrove). This may lead to different designs and differ- 399
 374 ent ways of construction and operation. 400

375 Stable sandy coasts usually exist thanks to a sediment 401
 376 source, often a river or an eroding cliff. If this source 402
 377 is reduced, for instance by damming upstream, or by fixa- 403
 378 tion of the cliff, the coast will tend to erode. One exam- 404
 379 ple is the Yellow River Delta, where the sediment source 405
 380 was first fixed in place by embanking the river, and sub- 406
 381 sequently reduced by a dam-induced change of the dis-

charge regime (Figure 9), followed by a coarsening of the 382
 bed, both of which bring down the rivers sediment trans- 383
 port capacity. As a consequence, the past rapid build-out 384
 of the delta was first concentrated around one location (the 385
 fixed river mouth) and later dropped dramatically, came 386
 to a standstill and even turned into erosion (e.g., NASA, 387
 2013). Other parts of the delta coast were cut off from 388
 their sediment source and eroded rapidly, in some places 389
 over a large distance (kilometres). Coastal nourishment 390
 and fixation by vegetation may be an option here, but this 391
 requires thorough reading of the system, i.e. consideration 392
 of the local situation, with very fine and easily erodible 393
 sediment and a high groundwater salinity. 394

Other examples of dramatic coastal erosion can be found 395
 on tropical mud coasts where the natural mangrove protec- 396
 tion has been removed, for instance in order to build fish 397
 ponds. Figure 10 shows an example of the north coast of 398
 Java near Demak, Indonesia, where heavy erosion started 399
 after the fish ponds had been abandoned. Given the many 400
 ecosystem services provided by mangrove forests, their res- 401
 toration seems attractive here. Many failures of man- 402
 grove replantation schemes (e.g. Primavera and Esteban 403
 (2008); Lewis III (2009)), however, have shown that this 404
 is nowhere near a trivial task. For the replanted system to 405
 survive it is crucial to have the right combination of coastal 406
 morphology (with a concave downward profile), wave con- 407
 ditions, tidal motion, fresh groundwater availability, sedi-

Figure 9: Time-evolution of the annual runoff (top panel; after Grafton et al., 2013) and sediment discharge (after Wang et al., 2011) at Lijin Hydrological Station, Lower Yellow River, China.

Figure 10: Coastal degradation between 2003 and 2013 near Demak, Indonesia (courtesy J.C. Winterwerp.).

409 ment supply and plant species (Winterwerp et al., 2013).
 410 This is another example of the necessity to read the local
 411 natural system, as it is now and as it has been in the past,
 412 and to adapt the design accordingly.

413 5. BwN in lake shore environments

414 5.1. Example: Lake IJssel Shore Nourishment

415 In 2008, a State Committee advised the Netherlands gov-
 416 ernment on flood safety and freshwater availability under
 417 a scenario of accelerated sea level rise (Delta Committee,
 418 2008). Part of this advice concerned the Lake IJssel, the
 419 inland freshwater lake that was created by closing off the
 420 Zuiderzee in 1932. The Committee advised to gradually
 421 raise the lake level along with the rising sea level, such
 422 that one could keep on discharging surplus water by free
 423 outflow. Although in the meantime this idea has been
 424 abandoned in favour of increased pumping capacity, the
 425 suggestion has raised the awareness of terrain managers
 426 of the former coastal saltmarshes, now valuable freshwa-
 427 ter wetlands which protect the dikes behind them against
 428 wave attack. They realized that these wetlands require
 429 maintenance, in order to be ready for stronger variations
 430 of the lake level, to combat ongoing subsidence and to en-
 431 able the vegetation to rejuvenate.

432 Although southwesterly winds have a considerable fetch
 433 here and local waves and water level set-up can be signifi-
 434 cant, the lake shores can be categorized as low-dynamic.
 435 This means that nourishing these shores would lead to
 436 a slow supply of sediment to the coastline, exactly what
 437 is needed to maintain these wetlands without destroying
 438 their vegetation.

439 In 2011 and 2012, respectively, small-scale shoreface nourish-
 440 ments were performed at two locations (Workumer-
 441 waard and Oudemirdumerklif) on the northwesterly shore

Figure 11: Design of the Workumerwaard nourishment experiment (grey rectangle: nourishment footprint; brown line: sand retaining pole screen); the primary flood defence, a dike, lies outside the photo to the right.

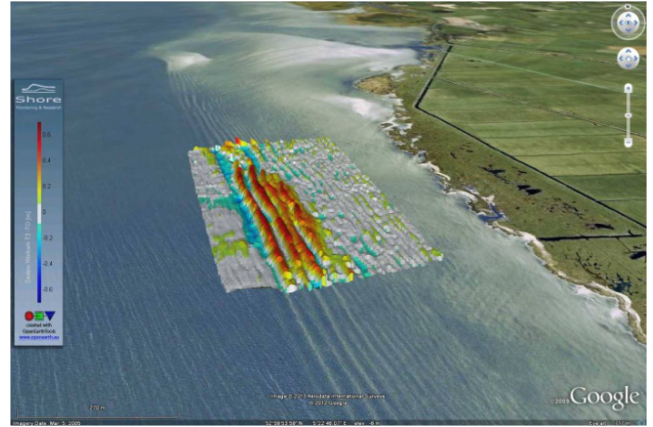

Figure 12: Bed topography after 1 year; warmer colours represent higher bed levels (courtesy Ane Wiersma); note the pole screen is not shown in this picture

442 of the lake. Figure 11 and Figure 12 show the develop-
 443 ment of the Workumerwaard nourishment, which involved
 444 some 30.000 m³ of sand. Although after the first year the
 445 nourished sand has hardly reached the shoreline, morpho-
 446 dynamic activity is clearly present, as the original hump
 447 has dispersed into a number of sand waves which are in line
 448 with the natural bed topography. Recent visual observa-
 449 tions suggest that the sand is moving northward, along
 450 with the net longshore drift, and is trapped in the lee of
 451 the pole screen.

452 At this location, reading nature boiled down to (1) real-
 453 izing that the wetlands had to remain in open connec-
 454 tion with the lake in order to keep their unique character,
 455 (2) concluding that the wetland vegetation had reached
 456 a climate stage and would need rejuvenation in order to
 457 restore diversity and vitality, (3) interpreting the natural
 458 sand waves on the subaqueous shore as a signal of morpho-
 459 dynamic activity that might bring nourished sediment on-
 460 shore, and (4) realizing that the prevailing longshore drift
 461 will tend to carry the sand further north, so that a sedi-
 462 ment retaining structure is needed.

463 Thinking differently means here the recognition that the
 464 wetlands are not only valuable from an ecological and
 465 recreational point of view, but also have the capability
 466 -when properly managed- to keep the dikes behind them
 467 from being strengthened. People acted differently here be-
 468 cause they decided not to strengthen the dike (and proba-
 469 bly let the wetlands get drowned) or build a protection
 470 levee along the shore (and probably destroy the wetlands'
 471 character), but to opt for slow sand nourishment. And
 472 they interacted differently because this project was devel-
 473 oped by experts from various disciplines, together with
 474 a variety of stakeholders and the local administration. At
 475 another location, Hindeloopen, this stakeholder involve-
 476 ment even led to a drastic change of plans, to the effect
 477 that for the time being no nourishment will be made, at
 478 all.

479 5.2. More general applicability

480 The example above concerns an existing, more or less nat-
481 ural foreshore. Such features are not always available in
482 lakes. Lakes in soft sediment environments like deltas tend
483 to expand in the direction of the prevailing winds. As this
484 process continues, they become more susceptible to wind-
485 induced water level variations, especially at the eroding
486 end. Also, floods in adjacent rivers may cause flood prob-
487 lems. Tai Lake, near Shanghai in China, for instance, lies
488 close to the Yangtze River and well below typical flood
489 levels in that river (Gong and Lin, 2009).

490 This shows that flood protection is an issue for the riparian
491 areas of such delta lakes. If the water from the lake has
492 to be kept out, dike building is an obvious way to achieve
493 this. If the subsoil is soft, however, like in the case of a
494 dike built on peat, the soil's carrying capacity may limit
495 the dike height. Also, subsoils with sandy streaks, e.g.
496 remainders of old streams and creeks, may give rise to
497 piping, i.e. the formation of sediment conveying seepage
498 channels which undermine the dike (e.g. De Vries et al.
499 (2010)).

500 The height of a traditional dike is determined to a significant
501 extent by wave overtopping restrictions, the width by
502 geomechanical stability requirements and the need to extend
503 the seepage length in order to prevent piping. As an
504 alternative to dike raising, one may consider designs that
505 reduce the wave attack and increase the stability and the
506 seepage length in another way. Depending on the local
507 situation, a shallow vegetated foreshore may be such an
508 alternative (Figure 13).

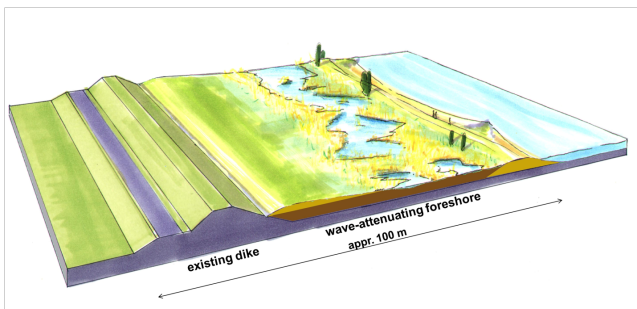

Figure 13: Artist impression of a lacustrine shallow foreshore in front of a traditional dike; the dark brown material is clayey, in order to prevent seepage; the light brown material is sandy, as a buffer against erosion (courtesy: Bureau Stroming)

509 Both the shallowness of the foreshore and the vegetation
510 on top of it attenuate incoming waves before they reach
511 the dike. A clayey substrate hampers seepage, hence in-
512 creases the effective seepage length. Such foreshores can
513 carry valuable ecosystems which provide a large number of
514 additional services, such as water purification (helophytes;
515 also see Figure 14), breeding, feeding and resting grounds
516 for a variety of species (among which migratory birds),
517 carbon sequestration and biomass production. It forms

Figure 14: Some lakes have severe water quality problems, such as algal blooms (photo from Tai Lake, China)

518 an alongshore connection between ecosystems that were
519 separated before and it provides space for a variety of re-
520 creation activities.

521 This, too, is not a panacea. If excessive rainfall is the main
522 cause of flooding, for instance, effective drainage is more
523 important than keeping the water out. This illustrates,
524 once again, the importance of reading and understanding
525 the local environment.

6. BwN in estuarine environments 526

6.1. Example: Eastern Scheldt Oyster Reefs 527

528 Bio-architects or ecosystem engineers are species that
529 modify their habitat, to their own benefit and that of other
530 species (e.g. Bouma et al. (2009)). Oysters and coral are
531 examples, they build reefs that provide habitat to a wide
532 range of others species. Apart from this effect on their
533 own habitat and that of other species, the activities of
534 bio-architects may have other positive effects, such as sed-
535 iment trapping and coastal protection. This makes these
536 species interesting from a BwN point of view. In temperate
537 climate zones, oyster reefs may be used to prevent erosion

538 and saltmarsh to trap sediment and attenuate waves. In a
539 tropical climate, mangrove forests, seagrass meadows and
540 coral reefs, often in combination, may help stabilizing and
541 protecting coasts.

542 A set of experiments with oyster reefs for the protection
543 of eroding intertidal shoals was performed in the Eastern
544 Scheldt, the Netherlands. These shoals are consistently
545 losing sediment to the gullies after the construction of a
546 storm surge barrier in the mouth of the estuary and a
547 number of auxiliary works have reduced the tidal amp-
548 litude by about 20% and the tidal prism in the mouth by
549 some 25% (e.g., [Elkema, 2013](#)). This loss of intertidal
550 area, together with the flattening of the shoals by wave
551 action, is detrimental to the populations of residential and
552 migratory birds, which use this area for feeding, resting
553 and breeding.

554 One way to interrupt the sediment transport from the
555 shoals into the gullies would be to create oyster reefs on
556 the shoal edges. This raises the question how to establish
557 live oyster reefs at the right locations. Since oyster shells
558 are the perfect substrate to settle on for juvenile oysters
559 (spat), gabions (iron wire cages) filled with oyster shells
560 ([Figure 15](#)) were placed on the shoal edges at various loca-
561 tions, first in small patches, later on in larger strips (typic-
562 ally 10 m wide and a few hundreds of metres long). After a
563 few years ([Figure 16](#)) we can conclude that this approach
564 can work, provided that the locations of the gabions be
565 carefully selected (see [oesterriffen.flyer.uk.pdf](#)).

Figure 15: Placement of gabions with oyster shells (courtesy Tom Ysebaert)

566 In this case, the natural processes were carefully analysed
567 and interpreted. The reduction of the tidal motion has
568 weakened the hydrodynamic forces building up the shoals
569 and has given room to the erosive action of locally gen-
570 erated waves. This explains why the shoals tend to be
571 ‘shaved’ off almost horizontally. The sediment eroded from
572 the tops of the flats ends up in the nearest deeper water,
573 so on the subtidal banks of the gullies. This means that
574 there are no mechanisms to carry this sediment further
575 away, and that if one would manage to keep the sediment

Figure 16: Successful oyster reef after one year (courtesy: Tom Ysebaert)

576 on top of the shoals it would probably stay there. This ex-
577 plains why oyster reefs on the shoal edges may help. The
578 ecosystem was also read carefully: oyster spat settling pref-
579 erentially on oyster shells, oyster reefs being more resistant
580 than mussel banks, for instance, because oysters glue their
581 shells together and mussels use a kind of threads to con-
582 nect to each other. Environmental conditions necessary
583 for a live oyster reef to establish and survive (wave expos-
584 ure, nutrient flows, risk of sand burial, risk of macroalgae
585 preventing spat settlement, ect.) were also carefully con-
586 sidered.

587 Here, too, thinking, acting and interacting were unusual.
588 Even though blocking shoal erosion may be considered
589 as an end-of-pipe measure (the real causes of the erosion
590 are not removed), using biological elements to achieve an
591 engineering goal, viz. erosion prevention, is a change in
592 thinking. Moreover, if the reefs are viable in the long run,
593 they will also be able to adapt themselves to a changing
594 sea level. This is a capability beyond what traditional en-
595 gineering structures can deliver. The design constitutes a
596 different way of acting. The placement of the gabions is
597 hardly intrusive (no digging, mostly indigenous compo-
598 nents). The ironwire gabions will corrode quickly in this ag-
599 gressive environment, so after some time the system relies
600 on the ability of the oyster reef to sustain and rejuvenate
601 itself. This is a different from traditional engineering, with
602 its focus on durable structures.

603 Finally, different experts (apart from technicians also
604 physicists, ecologists and social scientists) and different
605 stakeholders (apart from Rijkswaterstaat also [NGOs](#), fish-
606 ermen, etc.) were involved in the decision making process.
607 Moreover, coastal defence experts keenly followed the ex-
608 periments, because of the potential positive effects on the
609 wave-attenuating and dike-stabilizing function of shallow
610 shore-connected shoals.

611 6.2. More general applicability

612 Intertidal areas are found in estuaries around the world
 613 and usually they are of great value, environmentally, but
 614 also from an economic point of view (flood protection,
 615 land reclamation, aquaculture, etc.). Many of these es-
 616 tuaries, however, suffer from a reduced sediment supply,
 617 due to river damming, sand mining and excessive water
 618 offtake from the river that debouches through the estuary.
 619 The Yangtze River, with its many thousands of dams
 620 (Yang et al., 2011), is just one example, but there are
 621 many others. Many estuaries also have been deprived
 622 from their inter- and supra-tidal storage area, with severe
 623 consequences, not only for extreme surge levels and flood
 624 risks (Temmerman et al., 2013), but also for suspended
 625 sediment import and environmental quality (Winterwerp
 626 et al., 2013). Before the sediment supply to the Yangtze
 627 Estuary was drastically reduced, the islands and shoals
 628 in the Yangtze Estuary would build out rapidly, enabling
 629 consecutive reclamations of large pieces of land to meet
 630 the urgent need for space in this part of China (Fig-
 631 ure 17).

Figure 17: Consecutive reclamations of accreted marsh on East Chongming Island, Yangtze Estuary, China.

632 At present, the shoals in the estuary tend to erode. An
 633 early indicator of this tendency is the cross-shore profile,
 634 which has turned in recent years from concave upward to
 635 convex upward (Yang et al., 2011); also see Figure 18.
 636 A dense and vital vegetation canope (in this case a com-
 637 bination of endemic *Scirpus* and imported *Spartina*) can
 638 slow down this process (Yang et al., 2008), but cannot re-
 639 move the principal cause, viz. the lack of sediment supply
 640 from upstream. Whether ecosystem-engineers like oysters
 641 or mussels can provide a solution here remains to be seen,
 642 given the intense fisheries activity in this area. Moreover,
 643 the need for space creates pressure from society to reclaim
 644 more land, be it not at East Chongming Island, then in
 645 other parts of the estuary, and be it not above Mean Sea
 646 Level (MSL), then below it (cf. Chen et al., 2008). The lat-
 647 ter requires dike construction below MSL, which is bound
 648 to aggravate erosion in front of the dike. Clearly, not only
 649 the natural system needs to be read to find an adequate
 650 solution, but also the socio-economic system.

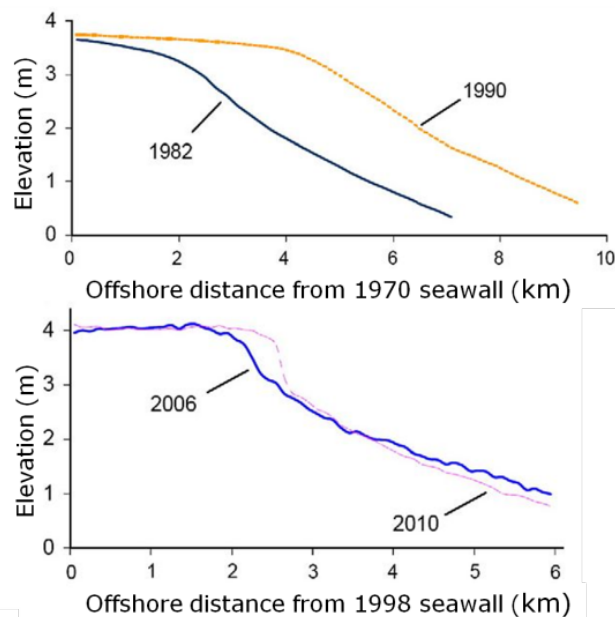

Figure 18: Cross-shore profile evolution at East Chongming Island, China (from: Yang et al. (2011)).

7. Dredging induced turbidity

652 Dredging, instrumental to many hydraulic engineering
 653 works, often leads to environmental concerns because of
 654 the turbidity it induces. This may harm valuable eco-
 655 systems, such as coral reefs in tropical areas, or shellfish
 656 reefs in moderate climate zones. So far, regulations used
 657 to focus on the sediment flux released from the dredging
 658 equipment, rather than on the actual impact on the eco-
 659 system. BwN proposes to reverse the order, starting from
 660 the ecosystem's vulnerability and working one's way back
 661 to the dredger. This enables optimization of the dredging
 662 operation.

Species response trajectory as a function of stress level and response time

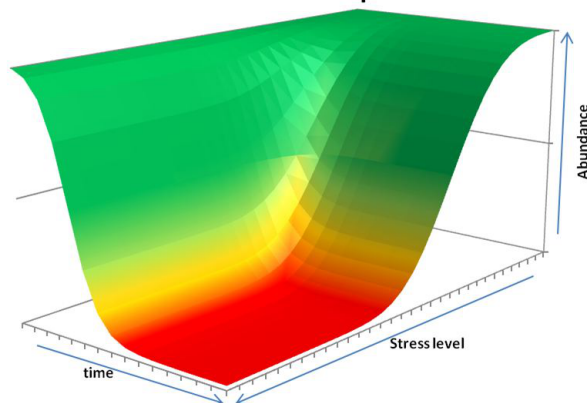

Figure 19: Species response trajectory for tropical seagrass (source: EcoShape, 2012)

663 A useful tool to assess ecosystem vulnerability are species
 664 response trajectories for the key species (Figure 19), de-
 665 scribing the abundance of a species as a function of stress
 666 level and exposure duration. Given a certain ecosystem
 667 and the hydrodynamic and sedimentologic conditions in
 668 its surroundings, one can work out the maximum allow-
 669 able sediment release at every location and every point in
 670 time using a sediment dispersion model. Figure 20 shows
 671 a screen shot of a dredging support tool in which this
 672 has been implemented. The green dots indicate locations
 673 where exposure to turbidity is predicted to remain below
 674 predefined threshold levels. The tools supports planning
 675 the dredging operation such that this is secured.

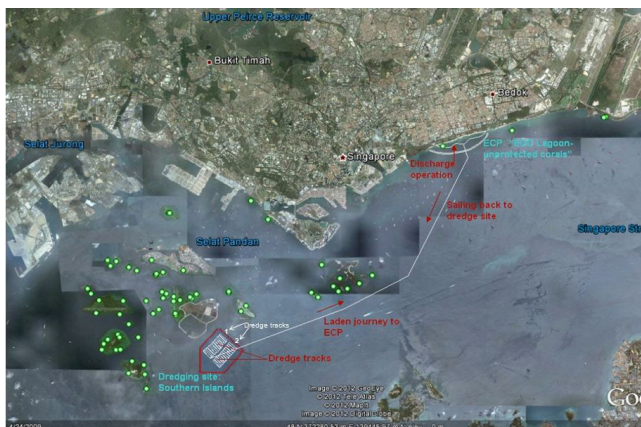

Figure 20: Screenshot of a dredging support system applied to a dredging operation near Singapore.

676 8. Discussion

677 8.1. Translation to practice

678 The above examples are just a selection of applications
 679 and application potential of the BwN-principles and design
 680 steps. Together they cover the range of applications
 681 outlined in Section 2. Many more examples are de-
 682 scribed by Waterman (2008), on the EcoShape website
 683 <http://www.ecoshape.nl>, in the BwN-booklet (De Vriend
 684 and Van Koningsveld, 2012) and in the BwN-design
 685 guideline (EcoShape, 2012). For new insights acquired
 686 from experiments and pilot projects to be used in prac-
 687 tice, translation to practical usability is crucial. This
 688 goes far beyond writing papers in scientific or professional
 689 journals or presenting material at conferences and work-
 690 shops. It requires a complete reworking of the material
 691 into guidelines for practical use, user-friendly tools, tuto-
 692 rials, low-threshold access to data and models, examples of
 693 earlier projects, ready-to-use building blocks, etc.

694 In the Dutch BwN innovation program (2008-2012) a signi-
 695 ficant part of the effort was spent to this reworking activi-
 696 ty. It has led to a wiki-like environment, accessible via
 697 the EcoShape-website mentioned above, which includes

698 all these elements and contains a wealth of information.
 699 Based on feedback from users and continued input from
 700 ongoing and new projects and experiments, this wiki is to
 701 be improved further.

702 8.2. Dissemination and outreach

703 The concept underlying BwN has been taken up by vari-
 704 ous other organisations. In the United Kingdom (UK),
 705 managed realignment, i.e. realignment of flood defences in
 706 such a way that there is more room for flood water stor-
 707 age and at the same time for nature, is basically a form of
 708 building with nature (e.g. Garbutt et al. (2006)). The
 709 World Association for Waterborne Transport Infrastruc-
 710 ture (PIANC) supports a similar movement named ‘Work-
 711 ing with Nature’ (see PIANC, 2013). The US Army Corps
 712 of Engineers (USACE) promotes the use of dredged mate-
 713 rial to create room for nature areas in the coastal zone: ‘En-
 714 gineering with Nature’ (Bridges et al., 2008). Also in Bel-
 715 gium, there are plans for extensive multi-functional ‘soft
 716 engineering’ in front of the North Sea coast of Flanders (see
 717 Vlaamse Baaien, 2013). Finally, the European Commis-
 718 sion (EC) has included the concept in its Green Infrastruc-
 719 ture Strategy (see European Commission, 2013).

720 Yet, mainstreaming the approach in practical hydraulic
 721 engineering projects still meets several obstacles. Some
 722 of these have to do with conservatism and risk-aversion,
 723 but others are associated with the economic point of view
 724 and the prevailing legislation. When considering only the
 725 short-term economics of adding sand to the backbeach and
 726 the dune area, the Delfland Sand Engine may be economi-
 727 cally suboptimal, as nourishing small amounts whenever
 728 necessary may well be cheaper. But from a longer-term
 729 and multi-functional perspective, mega-nourishments may
 730 just as well be economically attractive. Moreover, BwN
 731 requires investing time and money into knowing how the
 732 natural system -including the ecosystem- functions, an in-
 733 vestment that pays off later, but possibly not as directly
 734 as a traditional hard engineering solution.

735 If, like in the European Union (EU), legislation forces all
 736 government-funded infrastructural projects to be interna-
 737 tionally tendered, innovative pre-competitive experiments
 738 and pilot projects tend to be out-competed by traditional
 739 approaches of which the uncertainties are perceived to be
 740 less. Another example of the effect of prevailing rules
 741 concerns the assessment of the flood defence systems in
 742 the Netherlands, which excludes shallow foreshores. This
 743 renders shallow-foreshore solutions for flood defences use-
 744 less.

745 9. Conclusions

746 The existing experiments, pilot projects and showcases
 747 show that the BwN approach works, provided that one

748 thinks, acts and interacts accordingly. Knowing the nat- 806
749 ural biotic and abiotic environment in which an infrastruc- 807
750 tural functionality is to be realized, as well as knowing 808
751 how the relevant social system functions, is a necessity for 809
752 this approach to be successful. This applies in Europe, as 810
753 well as in other countries around the world, as shown by 811
754 the examples in Asia and the United States of America 812
755 (USA). Initiatives in different countries and international 813
756 organisations are merging into an international movement, 814
757 but mainstreaming the approach in hydraulic engineering 815
758 practice still meets a number of obstacles. They need to 816
759 be overcome in the next few years in order to have this 817
760 approach broadly implemented. 818

761 10. Acknowledgements

762 Except for Room for the River, the examples described 820
763 herein were part of the 2008-2012 BwN innovation pro- 821
764 gramme, which was funded jointly by the partners of the 822
765 EcoShape consortium, the Netherlands government, the 823
766 European Fund for Regional Development and the Muni- 824
767 cipality of Dordrecht. The authors are indebted to the 825
768 many colleagues who have realized these projects. 826
